

Modern C++ Programming

7. C++ OBJECT ORIENTED PROGRAMMING I

Federico Busato

University of Verona, Dept. of Computer Science
2020, v3.01

1 C++ Classes

- RAII
- Class Hierarchy
- Inheritance Attributes

2 Class Constructor

- Default Constructor
- Initialization List
- Delegate Constructor
- `explicit` Keyword

3 Copy Constructor

4 Class Destructor

5 Initialization and Defaulted Members

- Uniform Initialization
- Initialization Syntax
- Defaulted Constructor
- Zero-initialization

6 Class Keywords

- `this`
- `static`
- `const`
- `mutable`
- `using`
- `friend`
- `delete`

C++ Classes

C++ Classes

C/C++ Structure

A **structure** (`struct`) is a collection of variables of different data types under a single name

C++ Class

A **class** (`class`) extends the concept of structure to hold data members and also functions as members

Class Member/Field

The data within a class are called *data members* or *class field*.
Functions within a class are called *function members* or *methods* of the class

struct vs. class

Structures and classes are *semantically* equivalent. In general, `struct` represents *passive* objects, while `class` *active* objects

Holding a resource is a class invariant, and is tied to object lifetime

Implication 1: C++ programming language does not require the garbage collector!!

Implication 2: The programmer has the responsibility to manage the resources

RAII Idiom consists in three steps:

- Encapsulate a resource into a class (constructor)
- Use the resource via a local instance of the class
- The resource is automatically released when the object gets out of scope (destructor)

Struct declaration and definition

```
struct A;      // struct declaration

struct A {    // struct definition
    int x;    // data member
    void f(); // function member
};
```

Class declaration and definition

```
class A;      // class declaration

class A {    // class definition
public:      // visibility attribute
    int x;    // data member
    void f(); // function member
};
```

Struct/Class function declaration and definition

```
struct A {  
    void g();      // function member declaration  
  
    void f() {    // function member declaration  
        std::cout << "f"; // and inline definition  
    }  
};  
  
void A::g() {    // function member definition  
    std::cout << "g"; // (not inline)  
}
```

```
struct B {
    void g() { std::cout << "g"; }
};

struct A {
    int x;
    B b;
    void f() { std::cout << "f"; }
    using T = B;
};

int main() {
    A a;
    std::cout << a.x;
    a.f();
    a.b.g();
    A::T obj; // equal to "B obj"
}
```

Child/Derived Class or Subclass

A new class that inheriting variables and functions from another class is called a **derived** or **child** class

Parent/Base Class

The *closest* class providing variables and function of a derived class is called **parent** class

Extend a base class refers to creating a new class which retain characteristics of the base class and *on top it can add* (and never remove) its own members

Syntax:

```
struct DerivedClass : [<inheritance>] BaseClass {  
    ...  
};
```

```
#include <iostream>

struct A { // base class
    int value = 3;
};

struct B : A { // B inherits from A (B extends A) (B is child of A)
    int data = 4;
    int f() { return data; }
};

struct C : B { // C extends B (C is child of B)
};

int main() {
    A base;
    B derived1;
    C derived2;
    std::cout << base.value; // print 3
    std::cout << derived1.data; // print 4
    std::cout << derived2.f(); // print 4
}
```

`private`, `public`, and `protected` inheritance

- **public:** The public members can be accessed without any restriction
- **protected:** The protected members of a base class can be accessed by its derived class
- **private:** The private members of a class can only be accessed by function members of that class

Member declaration		Inheritance		Derived classes
public protected private	→	public	→	public protected \ private
public protected private	→	protected	→	protected protected \ private
public protected private	→	private	→	private private \ public

- structs have default **public** members
- classes have default **private** members

```
#include <iostream>
using namespace std;

class A {
public:
    int var1 = 3;
    int f() { return var1; }
protected:
    int b;
};

class B : public A { // without public, B inherits
};                  // the data member "var1" and f()
                   // as private members

int main() {
    B derived;
    cout << derived.f(); // print 3
    // cout << derived.b; // compile error!! protected
}
```

Class Constructor

Class Constructor

Constructor [ctor]

A **constructor** is a *special* member function of a class that is executed when a new instance of that class is created

- A constructor is always named as the class
- A constructor have no return type
- A constructor is supposed to initialize all the data members of a class
- We can define multiple constructors (different signatures)

Class constructors are never inherited. *Derived* class must call a *Base* constructor before the current class constructor

Class constructors are called in order of declaration
(C++ objects are constructed like onions)

Class Constructor (Examples)

```
#include <iostream>

class A {
    int x;
public:
    A(int x1) : x(x1) {    // constructor
        std::cout << "A";
    }
};

class B : A {
public:
    B(int b1) : A(b1) { std::cout << "B"; }
};

int main() {
    A a(1);    // print "A"
    B b(2);    // print "A", then print "B"
    A c = {1}; // initialization, print "A"
    A d {1};   // initialization (C++11), print "A"
}
```

Default Constructor

Default Constructor

The **default constructor** is a constructor with no arguments

Every class has always either an *implicit* or *explicit* default constructor

```
class A {  
public:  
    A()    {} // default constructor  
    A(int) {} // normal constructor  
};
```

if a *user-provided constructor* is defined while the *default constructor* is not, the *default constructor* is marked as deleted

Example

```
struct A {}; // implicit-declared public default constructor

class B {
public:
    B() { // default constructor
        std::cout << "B";
    }
};

struct C {
    int& a; // implicit-deleted default constructor (next slide)
};

int main() {
    A a1; // call the default constructor
    // A a2(); // interpreted as a function declaration!!
    B b; // ok, print "B"
    B array[3]; // print three times "B"
    // C c; // compile error!! deleted
}
```

Deleted Default Constructor

The *implicit* default constructor of a class is marked as **deleted** if (simplified):

- It has a member of reference/`const` type
- It has a user-defined constructor
- It has a member/base class which has a deleted (or inaccessible, or ambiguous) default constructor
- It has a base class which has a deleted (or inaccessible, or ambiguous) destructor

Initialization List

Any data member should be initialized by constructors with the **initialization list** or by using **brace-or-equal-initializer** (C++11) syntax

const and **reference** data members must be initialized by using the *initialization list* or by using *brace-or-equal-initializer*

```
struct A {
    const char x;           // must be initialized
    int        y;
    int&       z;           // must be initialized
    A() : x('a'), y(3), z1(x) {} // initialization-list
};

struct A {
    const char y = 'a';    // brace-or-equal-initializer (C++11)
    int        x = 3;      // brace-or-equal-initializer (C++11)
    int&       z = y;      // brace-or-equal-initializer (C++11)
};
```

Member Initialization

```
struct A {  
    int      a = 3;           // not allowed in C++03  
    const int b = 3;         // not allowed in C++03  
  
    // int c { 3.3 };        // compiler error!! (narrowing)  
                             // uniform-initialization  
                             // should be preferred  
  
    static const int  d = 4; // also C++03  
  
    // static int      e = 4; // compiler error!! (-Wpedantic)  
  
    static const float f = 4; // only GNU extension (GCC)  
  
    static constexpr float g = 4; // correct  
};  
  
int A::e = 4; // ok
```

Delegate Constructor

The problem:

Most constructors usually perform identical initialization steps before executing individual operations

A **delegate constructor** (C++11) calls another constructor of the same class to reduce the repetitive code by adding a function that does all of the initialization steps

```
struct A {
    int    a1;
    float  b1;
    bool   c1;

    // standard constructor:
    A(int a1, float b1, bool c1) : a(a1), b(b1), c(c1) {}

    // delegate constructors:
    A(int a1, float b1)           : A(a1, b1, false)   {}
    A(float b1)                   : A(100, b1, false)  {}
};
```

explicit Keyword

explicit

The `explicit` keyword specifies that a constructor or conversion function does not allow implicit conversions or copy-initialization

```
struct A {
    A(int) {}
    A(int, int) {}
};

int main() {
    A a1 = 1;           // ok (implicit)
    A a2(2);           // ok
    A a3 {4, 5};       // ok. Selected A(int, int)
    A a4 = {4, 5};     // ok. Selected A(int, int)

    struct B {
        explicit B(int) {}
        explicit B(int, int) {}
    };

    // B b1 = 1;       // error!! implit conversion
    B b2(2);           // ok
    B b3 {4, 5};       // ok. Selected A(int, int)
    // B b4 = {4, 5}; // error!! implit conversion
    B b5 = (B)1;       // OK: explicit cast
}
```

Copy Constructor

Copy Constructor

Copy Constructor

A **copy constructor** is a constructor used to create a new object as a *copy* of an existing object

Every class always define an *implicit* or *explicit* copy constructors

```
struct A {  
    A()          {} // default constructor  
    A(int)       {} // user-provided constructor  
    A(const A&) {} // copy constructor  
}
```

Note: in class the implicit copy constructor is marked as private

Example

```
struct A {
    int size;
    int* array;

    A(int size1) : size(size1) {
        array = new int[size];
    }

    A(const A& obj) : size(obj.size) { // copy constructor
        for (int i = 0; i < size; i++)
            array[i] = obj.array[i];
    }
};

int main() {
    A x(100);
    A y(x);    // call "A::A(const A&)" copy constructor
}
```

Copy Constructor Usage

The copy constructor is used to:

- Initialize one object from another having the same type
 - Direct constructor
 - Assignment operator

```
A a1;  
A a2(a1); // Direct copy-constructor  
a1 = a2; // Assignment operator
```

- Copy an object which is *passed-by-value* as input parameter of a function

```
void f(A a);
```

- Copy an object which is returned as result from a function*

```
A f() {  
    return A(3); // * see RVO optimization  
}
```

Example

```
#include <iostream>
class A {
public:
    A() {}
    A(const A& obj) { std::cout << "copy" << std::endl; }
};

void f(A a) {}
A g() { return A(); };

int main() {
    A a;
    A b = a;    // copy constructor (assignment)
    A c(b);    // copy constructor (direct)
    f(b);     // copy constructor (argument)
    g();      // copy constructor (return value)
    A d = g(); // * see RVO optimization
}
```

Pass by-value and Copy Constructor

```
#include <iostream>
class A {
public:
    A() {}
    A(const A& obj) { std::cout << "expensive copy" << std::endl; }
};

class B : public A {
public:
    B() {}
    B(const B& obj) { std::cout << "cheap copy" << std::endl; }
};

void f1(B b) {}
void f2(A a) {}

int main() {
    B x;
    f1(x); // cheap copy
    f2(x); // expensive copy!! It calls A(const A&) implicitly
}
```

Deleted Copy Constructor

The copy constructor of a class is marked as **deleted** if (simplified):

- Every non-static class type (or array of class type) member has a valid (accessible, not deleted, not ambiguous) copy constructor
- Every base classes has a valid (accessible, not deleted, not ambiguous) copy constructor
- It has a base class with a deleted or inaccessible destructor
- The class has no move constructor (next lectures)

Class Destructor

Destructor [dtor]

A **destructor** is a member function of a class that is executed whenever an object is out-of-scope or whenever the delete expression is applied to a pointer to the object of that class

- A destructor will have exact same name as the class prefixed with a tilde (~)
- A destructor does not have any return type
- Each object has exactly one destructor
- A destructor is useful for releasing resources before the class instance goes out of scope or it is deleted

```
struct A {  
    int* array;  
  
    A() { // constructor  
        array = new int[10];  
    }  
  
    ~A() { // destructor  
        delete[] array;  
    }  
};  
  
int main() {  
    A a; // call the constructor  
    for (int i = 0; i < 5; i++)  
        A b; // call 5 times the constructor and the destructor  
    // call the destructor of "a"  
}
```

Class destructor is never inherited. *Base* class destructor is invoked *after* the current class destructor.

Class destructors are called in reverse order

```
struct A {
    ~A() { std::cout << "A"; }
};
struct B {
    ~B() { std::cout << "B"; }
};
struct C : A {
    B b;           // call ~B()
    ~C() { std::cout << "C"; }
};

int main() {
    C b; // print "C", then "B", then "A"
}
```

Initialization and Defaulted Members

Uniform Initialization (C++11)

Uniform Initialization `{}`, also called *list-initialization*, is a way to fully initialize any object independently from its data type

- **Minimizing Redundant Typenames**
 - In function arguments
 - In function returns
- Solving the “**Most Vexing Parse**” problem
 - Constructor interpreted as function prototype

To not confuse with narrowing conversion

Full details:

<http://mbevin.wordpress.com/2012/11/16/uniform-initialization/>

Minimizing Redundant Typenames

C++03

```
struct Point {  
    int x, y;  
    Point(int x1, int y1) : x(x1), y(y1) {}  
};  
  
Point add(Point a, Point b) {  
    return Point(a.x + b.x, a.y + b.y);  
}  
  
Point c = add(Point(1, 2), Point(3, 4));
```

C++11

```
struct Point {  
    int x, y;  
    Point(int x1, int y1) : x(x1), y(y1) {}  
};  
  
Point add(Point a, Point b) {  
    return { a.x + b.x, a.y + b.y }; // here  
}  
  
auto c = add({1, 2}, {3, 4}); // here
```

“Most Vexing Parse” problem

```
struct A {
    int a1, a2;
};
class B {
    int b1, b2;
public:
    B(A a) {}
    B(int x1, int x2) : b1(x1), b2(x2) {}
};
//-----

B g(A a) {           // "b" is interpreted as function declaration
    B b( A() );     // with a single argument A (*)() (func. pointer)
// return b;       // compile error!! "Most Vexing Parse" problem
}                  // solved with B b{ A{} };
//-----

struct C {
// B b (1, 2);     // compile error (struct)! It works in a function scope
    B b { 1, 2 }; // ok, call the constructor
};
```

Initialization Syntax

```
struct A {  
    A(char*) {} // conversion constructor:  
    A(int) {} // single-parameter constructor without  
}; // explicit specifier  
  
A a1(1); // direct initialization  
A a2{2}; // direct list initialization  
A a3 = 3; // copy initialization  
A a4 = {4}; // copy list initialization  
  
A a5 = A(5); // direct initialization,  
// then copy initialization  
  
A a6("a6"); // direct initialization  
// A a7 = "a6"; // copy assignment operator  
// (const char* to char*)  
A a7 = { "a6" }; // copy list initialization
```

In C++11, we can use the compiler-generated version of default/copy constructors `= default`

The **defaulted** default constructor has the same effect as a user-defined constructor with empty body and empty initializer list

When compiler-generated constructor is useful:

- Define any constructor different from the default constructor disables implicitly-generated default constructor
- Move default/copy constructors to `public`, `protected`, `private`

```
struct A {  
    int v;  
    A(int v1) : v(v1){} // delete implicitly-defined default ctor  
    A() = default;      // now A has the default constructor  
};  
  
class B : A { // default/copy constructor marked private  
public:  
    B()          = default; // default constructor now is public  
    B(const B&) = default; // copy constructor now is public  
}; // "B() = default" equal to "B() : A() {}"  
    // "B(const B&) = default" equal to  
int main() { // "B(const B& b) : A(b.v) {}"  
    B x, y;  
    x.v = 4 ;  
    y = x; // "y.v" has value 3  
}
```

Zero-initialization / default-constructor with the syntax `{}` or `= {}` applies to:

- **scalar types** (int, float, char, pointers, enums)
- **classes** (and structs) *without an explicit default constructor*, zero-initializing all class sub-objects recursively (members and base classes)
- **plain arrays** `T[]` with zero-initialization of `T`
- `new T`, `new T[]` call the explicit default constructor of `T` if available. Undefined values otherwise

```
struct A {
    int arr[5];
};

int a1;           // undefined value
int a2{};        // call default-constructor (zero)

int array1[10];  // undefined values
int array2[10] {}; // call default-constructor (zero)
int array3[10] = {}; // call default-constructor (zero)

A s1;           // undefined values
A s2{};        // arr: all zeros
```

See also Brace, brace!

```
struct B0 { int x; };
struct B1 { int x{}; };

struct B2 {
    int x;
    B2() {}
    B2(int x1) : x{x1}{}
};

struct B2 {
    int x;
    B2() = default;
};

auto b0 = new B0[10]; // x is undefined for all B0
auto b1 = new B1[10]; // x is zero for all B1
auto b2x = new B2[10]; // x is undefined for all B2
auto b2y = new B2[10]{1}; // x is 1 for the first B2,
// undefined for the others
auto b2z = new B2[10]{}; // undefined for all B2 (empty list)
auto b3 = new B3[10]; // x is zero for all B3
```

Class Keywords

this Keyword

this

Every object has access to its own address through the pointer

`this`

The `this` const pointer an implicit variable added to any member function. In general, it is not needed (and not suggested)

`this` is necessary when:

- The name of a local variable is equal to some member name
- Return reference to the calling object

```
struct A {  
    int x;  
    void f(int x) {  
        this->x = x; // without "this" has no effect  
    }  
    const A& g() {  
        return *this;  
    }  
};
```

static Keyword

The keyword `static` declares members (fields or methods) that are not bound to class instances. A **static** member is shared by all objects of the class

- A *static* member function can access only *static* class members
- A *non-static* member function can access *static* class members
- All *static* data is initialized to zero/default useless if no user-initialization is provided
- It can be initialized (defined) only once
- Non-const static data members cannot be `inline` initialized

```
#include <iostream>
struct A {
    int y = 2;
    static int x; // declaration (= 3 -> compile error)

    static int f() { return x * 2; }
    // static int f() { return y; } // error!! ("y" is non-static)
    int h() { return x; } // ok, ("x" is static)
};

int A::x = 3; // static variable definition

int main() {
    A a;
    a.h(); // return 3
    A::x++;
    std::cout << A::x; // print 4
    std::cout << A::f(); // print 8
}
```

Const member functions

Const member functions, or (**inspectors**), do not change the object state

Member functions without a `const` suffix are called *non-const member functions* or *mutators*

The compiler prevent callers from inadvertently mutating/changing the object data members with functions marked as `const`

```
class A {
    int x = 3;
public:
    int get() const {
        // x = 2;    // compile error!! class variables cannot
        return x; // be modified
    }
};
```

The `const` keyword is part of the functions signature. Therefore a class can implement two similar methods, one which is called when the object is `const`, and one that is not

```
class A {
    int x = 3;
public:
    int get1()      { return x; }
    int get1() const { return x; }
    int get2()      { return x; }
};

int main() {
    A a1;
    std::cout << a1.get1();    // ok
    std::cout << a1.get2();    // ok
    const A a2;
    std::cout << a2.get1();    // ok
    // std::cout << a2.get2(); // compile error!! "a2" is const
}
```

mutable Keyword

mutable

`mutable` members of *const* class instances are modifiable

Constant references or pointers to objects cannot modify that object in any way, except for data members marked `mutable`

- It is particularly useful if most of the members should be constant but a few need to be modified
- *Conceptually, `mutable` members should not change anything that can be retrieved from your class interface*

```
struct A {
    int      x = 3;
    mutable int y = 5;
};
int main() {
    const A a;
    // a.x = 3;    // compiler error!! (const)
    a.y = 5;     // ok
}
```

using Keyword

The `using` keyword can be used to change the *inheritance attribute* of member data or functions

```
class A {
protected:
    int x = 3;
};

class B : A {
public:
    using A::x;
};

int main() {
    B b;
    b.x = 3; // ok, "b.x" is public
}
```

friend Class

A `friend` class can access the private and protected members of the class in which it is declared as a friend

Friendship properties:

- **Not Symmetric:** if class `A` is a friend of class `B`, class `B` is not automatically a friend of class `A`
- **Not Transitive:** if class `A` is a friend of class `B`, and class `B` is a friend of class `C`, class `A` is not automatically a friend of class `C`
- **Not Inherited:** if class `Base` is a friend of class `X`, subclass `Derived` is not automatically a friend of class `X`; and if class `X` is a friend of class `Base`, class `X` is not automatically a friend of subclass `Derived`

```
class A; // class declaration

class B {
    int y = 3; // private
    int f(A a);
};

class A {
    friend class B;
    int x = 3; // private
    int f(B b);
};

    int B::f(A a) { return a.x; } // ok, B is friend of A
// int A::f(B b) { return b.y; } // compile error!! (not symmetric)

class C : B {
// int f(A a) { return a.x; } // compile error!! (not inherited)
};
```

friend Method

A non-member function can access the private and protected members of a class if it is declared a **friend** of that class

```
class A {
    int x = 3; // private

    friend int f(A a);
};

//'f' is not a member function of any class
int f(A a) {
    return a.x; // A is friend of f(A)
}
```

delete Keyword

delete Keyword

The `delete` keyword (C++11) explicitly marks a member function as deleted and any use results in a compiler error. When it is applied to *copy/move constructor* or *assignment*, it prevents the compiler from implicitly generating these functions

The default copy/move functions for a class can produce unexpected results. The keyword `delete` prevents these errors

```
struct A {
    A(const A& a) = delete;
};

// e.g. if a class uses heap memory
void f(A a) {} // the copy construct should be
               // written by the user -> expensive copy

int main() {
    // f(A()); // compile error!! (marked as deleted)
}
```
